PHYTOGENIC mounds (nebkhas) formed by halophytes are widely distributed in coastal and desert environments. Such nebkhas provide loci for geochemical and biological activities that influence ecosystem processes and function. Seasonal variation in soil and bacterial properties were investigated within the nebkhas under the canopy of *Halocnemum strobilaceum* and in the surrounding unvegetated sites at salt marshes of Lake Manzala. The parameters measured include soil moisture, organic matter, total nitrogen and phosphorus, pH, electrical conductivity (EC), and bacterial community and enzyme characteristics. Enrichment ratios for soil salinity and nutrients were evaluated to indicate the salinity and fertility islands within nebkhas. Soil moisture content showed significant differences between the different seasons with the highest value in winter (16.55%) at unvegetated control site. Soil electrical conductivity, total nitrogen and phosphorus had their significantly higher values in nebkhas during autumn. The enrichment values for the measured soil parameters ranged from 0.31 to 4.09 in the four seasons which indicates a clear accumulation effect for soil nutrients and salts within the nebkhas under the canopy of *H. strobilaceum*. Bacterial abundance was consistently higher in nebkhas through all seasons. Eleven genera of bacteria belong to Firmicutes, Actinobacteria and proteobacteria phyla were recorded in nebkha and unvegetated sites. These genera varied in their occurrence between the two locations and the four seasons. It can be concluded that the formation of nebkhas by halophytic vegetation have noticeable effects on accumulation of soil salinity and fertility during different seasons that affect bacterial abundance and activity in coastal environment.

Keywords: *Halocnemum strobilaceum*, Nebkha, Amylase, Carboxymethylcellulase, Bacteria.

Introduction

Halophytes are promising plant resources in arid and coastal zones because they can tolerate high saline conditions. Such salt-adapted plant resources are commonly found along coastal plains (Glenn et al., 1991). In arid and semi-arid ecosystems, halophytic communities have many influences on the physical and chemical properties of rhizosphere soil, litter decomposition, and the carbon-nitrogen cycle (Han et al., 2007 and Yan et al., 2010).

Soil microorganisms are important members of terrestrial ecosystems. Microorganisms are sensitive to external environmental changes with the ability to change the community structure (White et al., 1979). These microorganisms are responsible for much of soil organic matter turn over and drive soil nutrient cycling in most ecosystems. The relative abundances of microbial community groups (e.g., fungal and bacterial groups) can vary along environmental gradients (Waldrop & Firestone, 2006). Along with this variation in microbial community composition, microbial function, as measured through nutrient

turnover, changes may also occur on a seasonal basis (DeForest et al., 2009). Previous studies examining relationship between vegetation patchiness and microbial communities were conducted in a forest ecosystem (Pennanen et al., 2001) or volcanic desert ecosystem (Yoshitake et al., 2013). However, studies on examining the bacterial communities and activity associated with patchiness of halophytic vegetation in an extreme saline-alkali wet land are rare.

In Egypt, the halophytic vegetation is existing in two types of salt marshes namely coastal along the Red Sea and Mediterranean Sea, and inland in the oases and inland desert (Zahran, 1982; El-Khouly & Zahran, 2002 and El-Bana, 2006). The perennial halophytic shrub *Halocnemum strobilaceum* (Pall.) Bieb. is among the dominant arido-active species in the salt marshes of Egypt including Lake Manzala (Zahran & Willis, 2009 and El-Bana, 2015). *H. strobilaceum* is an obligate halophyte that accumulate wind- or water-borne sediments within and/or around its canopy forming phytogenic mounds (Nebkhas). Nebkhas improve soil properties, microclimate and biodiversity by capturing and preserving soil moisture, nutrients and propagules (Jackson & Caldwell, 1993; Hesp & McLachlan, 2000; Dougill & Thomas, 2002 and El-Bana et al., 2002b; 2003; 2007).

In the current study, the impact of nebkhass formed by *H. strobilaceum* on soil moisture, salinity, nutrients, and bacterial abundance and the soil enzyme activities in different seasons were evaluated at the salt marshes of Lake Manzala. Such information will improve our understanding of the role of halophytic communities in capturing resources and affecting microbial activity in harsh arid environments.

Materials and Methods

Study area

Study area is located on the eastern side of Lake Manzala, near El Manasra Village, on the road of Damietta- Port Said where three sites were selected for *H. strobilaceum* (Fig. 1). Lake Manzala represents the largest lake in the Nile Delta with a present area of 700 km², and average water depth of 1.0 m (Rasmussen et al., 2009). It is characterized by an arid climate with hot summer and mild winter. North (N), North-West (NW) and South-West (SW) winds together with El-Khamasin are responsible for the formation of sand dunes and other land forms of the area (Zahran & Willis, 2009). It is separated from the Mediterranean Sea by strip of land that is very narrow in several places and it is connected with the sea through Algamil outlet.

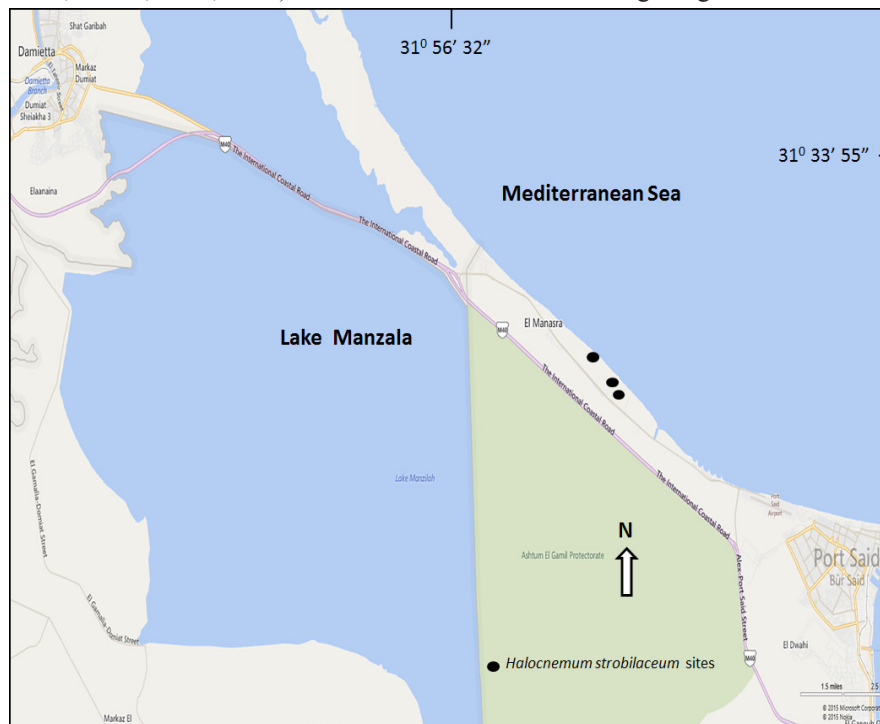

Fig. 1. Location of the study area and sites for sampling *Halocnemum strobilaceum* nebkhass at the salt marshes of Lake Manzala. (source © google maps).

Soil sampling and analysis

Sampling was done seasonally from autumn 2014 to summer 2015. Soil samples were collected from two different locations surrounding three individuals of *H. strobilaceum*: soil within nebkhas beneath the canopy (at about 20-30 cm distance from the main stem) and from open locations without vegetation (at 150-200 cm outside the canopy) as a control. At each selected plant individual, soil samples were collected from the four cardinal directions to form composite samples by hand auger at 0-20 cm depth. Soil samples were packed carefully in sterilized polyethylene bags and transported to the laboratory. Each composite soil sample was divided into two parts, one for determination of soil moisture content and bacteriological analysis and the other stored at 4 °C for chemical analysis.

Soil moisture content has been measured as the ratio of the mass of water present in sample to the mass of the sample after it has been dried at 105°C to constant weight (Gardner et al., 2000). Soil organic matter content was determined by the rapid wet oxidation method of Walkley & Black (1934) protocol as modified and described by Nelson & Sommers (1996). Total nitrogen was determined using modified Kjeldahl method (Jackson, 1967). Total phosphorus was measured using spectrophotometer according to Black et al. (1965). Soil pH and EC were measured by intelligent pH meter YK-2001 and Jenway 4510 electrical conductivity meter, respectively, at a soil/water ratio of 1:5.

Isolation and identification of bacteria

Soil suspension (0.1 mL) was spread onto Halophilic Nutrient Agar (LMG Medium 220; Atlas, 2010) plates with 3 different salt concentrations: 3%, 10%, and 20% for slight, moderate, extreme halophilic bacteria, respectively according to their salinity requirements, followed by incubation at 30°C. Isolates were morphologically, physiologically and biochemically identified at genus level according to Bergy's Manual of Systematic Bacteriology edition of vol. 2, 3, 4 and 5 (© 2005, 2009, 2010 and 2012 respectively). Gram reaction of each isolate was studied. The biochemical tests studied were catalase test, oxidase test (using MICROBACTTM oxidase detection strips), Starch hydrolysis, Cellulolytic activity (Kasana et al., 2008 and Antony et al., 2009), Acid from glucose fermentation, Growth on MacConkey

agar medium. Each isolate was tested for growth at 35°C and on Halophilic Nutrient agar medium with 0%, 10%, 20% NaCl.

Bacterial abundance

Total bacterial number was determined by direct counting under epifluorescence microscopy (Olympus BX53 U-RFL-T) according to Hobbie et al. (1977). Calculation of the number of cells per gram of soil was calculated as described by Polyanskaya et al. (2013).

Soil enzymes

Criteria for choosing enzyme assays were based on their importance in nutrient cycling and organic matter decomposition, and simplicity of the assay (i.e., potential to be adopted by commercial labs for routine soil testing). Amylase and Carboxymethylcellulase (CMCase) activities were detected using UNICO spectrophotometer at 550 nm according to Ross (1966) and Pancholy & Rice (1973), respectively.

Statistical analysis

The obtained data of soil and bacterial properties were subjected to analysis of variance (ANOVA) followed by Scheffe and T-tests to compare means for significance at the $p < 0.05$ level. Correlation coefficients between soil parameters and bacterial characteristics were performed by Pearson correlation coefficients. All statistical analyses were carried out using software SPSS for windows (SPSS Inc., Chicago, IL, USA; Version 16.0).

Results

Soil variables

The overall results of ANOVA analysis indicated significant differences in the measured soil properties between the four seasons (F-values, Table 1). Soil moisture recorded significantly its highest value in winter (16.55%) at unvegetated site, however it was 14.55% at the nebkhas under the canopy (Table 1). In summer, the values of moisture content were 5.98% and 6.05% in the soil of nebkhas and outside the canopy, respectively. Nebkhas at winter season attained significantly the highest value of organic matter content (0.84%) compared to their counterparts in other seasons (Table 1). However, summer season showed the lowest values of organic matter contents with 0.39% and 0.31% at nebkha and unvegetated sites, respectively. The total

nitrogen and phosphorus had their significantly higher values (1.2% and 0.43%, respectively) in nebkhas during autumn. Similarly, the highest value of electrical conductivity (6.27 mS/cm)

was in nebkhas during autumn. Soil pH ranged between 6.58 and 7.93 at nebkhas in summer and unvegetated sites in autumn.

TABLE 1. Mean values \pm standard error (second line) of soil properties at different seasons and microhabitats in *Halocnemum strobilaceum* community.

Enrichment ratios for soil variables in the four seasons

The enrichment ratios for soil variables differed significantly between the four seasons (Table 2). The enrichment values for the measured soil variables ranged from 0.31 to 4.09 in the four

seasons indicating a clear accumulation effect for soil nutrients and salts in the nebkhas under the canopy of *H. strobilaceum*. There were significant differences in enrichment values for soil moisture content, total phosphorus and soil salinity (EC) between the four seasons, with the highest values being found in the autumn.

TABLE 2. Enrichment ratios (E) of soil variables at the four seasons.

Soil variable	Season				F-value	P-level
	Autumn	Winter	Spring	Summer		
Soil moisture	1.26	0.88	0.58	0.99	11.42	0.001
	0.95	0.12	0.47	0.42

Soil bacterial characteristics

Overall, 11 genera were identified at the nebkha and unvegetated sites, with three phyla (Firmicutes, Actinobacteria and proteobacteria). Firmicutes phylum is presented by six genera including *Bacillus*, *Trichococcus*, *Listeria*, *Exiguobacterium*, *Lactobacillus* and *Planomicrobium*. Actinobacteria phylum includes four genera *Arthrobacter*, *Cellulomonas*, *Microbacterium* and *Corynebacterium*. However, the genus *Salinivibrio* belongs to proteobacteria phylum. The tested characteristics of these genera are presented in Table 3. *Bacillus*, *Arthrobacter*, *Cellulomonas* and *Listeria* were common at both locations (nebkhas and unvegetated sites), however *Microbacterium*, *Corynebacterium*, *Lactobacillus*, *Exiguobacterium* and *Planomicrobium* were recorded only in nebkhas. These genera showed seasonal variation in their occurrence (Table 3). For example, *Bacillus* was recorded in all seasons; but *Arthrobacter* and *Listeria* were observed in winter and spring. Furthermore, *Microbacterium* and *Exiguobacterium* were recorded only in summer season. Similarly, *Corynebacterium* and *Planomicrobium* were collected only in winter season. *Trichococcus* spp.' colonies are circular, off-white, flat, concentric, entire, translucent. Gram positive, motile and produced acid from glucose fermentation but didn't produce catalase and oxidase. Starch and cellulose were not hydrolyzed. Its growth on medium with 0% concentration of NaCl was occurred but not at 10% and 20%. This genus grew at unvegetated sites during autumn. Genus *Salinivibrio* was morphologically characterized with oval, white, flat, smooth, entire, opaque colony. Gram negative, motile, catalase, oxidase and acid from glucose fermentation were recorded. Its growth with pink colonies was observed on MacConker agar medium as well as on media with 0, 10 and 20 % of NaCl.

Bacterial total abundance per g fresh soil showed significant seasonal and spatial variations (Fig. 2). In all seasons, nebkhas had higher total bacterial counts compared to unvegetated sites. The highest total count (1.22×10^9 cells/g) was recorded in soil of nebkhas during summer season. A paired T-test showed that there were significant differences ($p < 0.05$) in the total bacterial abundance between the two sampling locations (nebkhas and unvegetated sites) in all four seasons (Fig. 2). Bacterial abundance was significantly negative correlated with soil organic matter content (Table 4).

Soil enzyme activities

Amylase enzyme had its lowest activity in winter which had the highest activity of carboxymethylcellulase enzyme (Fig. 3a, b). For amylase, nebkhas recorded significantly higher activities in autumn and summer, while it had lower activities in winter and spring (Fig. 3a). Carboxymethylcellulase activity of nebkhas was lower than unvegetated sites only in summer season only (Fig. 3b). Amylase enzyme was negatively correlated with soil moisture content at a significant level ($P < 0.01$). However, Carboxymethylcellulase enzyme activity showed a significant positive correlation with organic matter (Table 4).

Discussion

Vegetation types generally alter soil properties by nutrient cycling and litter decomposition. Consequently, the community of soil microorganisms can also be affected by variations in plant community root exudates (Sarig & Steinberger, 1994 and Zahran, 1997). In the current research, the nebkhas of the halophytic species *H. strobilaceum* showed variations in soil variables as well as in bacterial abundance and activity compared with surrounding unvegetated sites. Moisture content of soil is crucial for both plants and microorganisms that rely heavily on water in soils and water is essential for nutrient cycle (Yan et al., 2015). It has been documented that soil moisture content vary in both time and space, and consequently affect microbial activity and growth (Kieft et al., 1987). The moisture content in the soil of unvegetated sites was higher compared to that of nebkhas of *H. strobilaceum*. This could be related to the presence of extensive root system of this species that deplete moisture content by evapotranspiration within nebkhas (Batanouny & Batanouny, 1968 and Batanouny, 2001), and could be also due to the interception of rain fall by the canopy (Kröpfl et al., 2002). Considering temporal variation in soil moisture content, the highest values of moisture content for soil in the nebkhas were in winter while the lowest values were in summer. These results are in accordance with the seasonal patterns of precipitation along the Mediterranean Coast of Egypt, with rainfall concentrated in winter while summer is always rainless and with high temperature and evapotranspiration (Zahran & Willis, 2009).

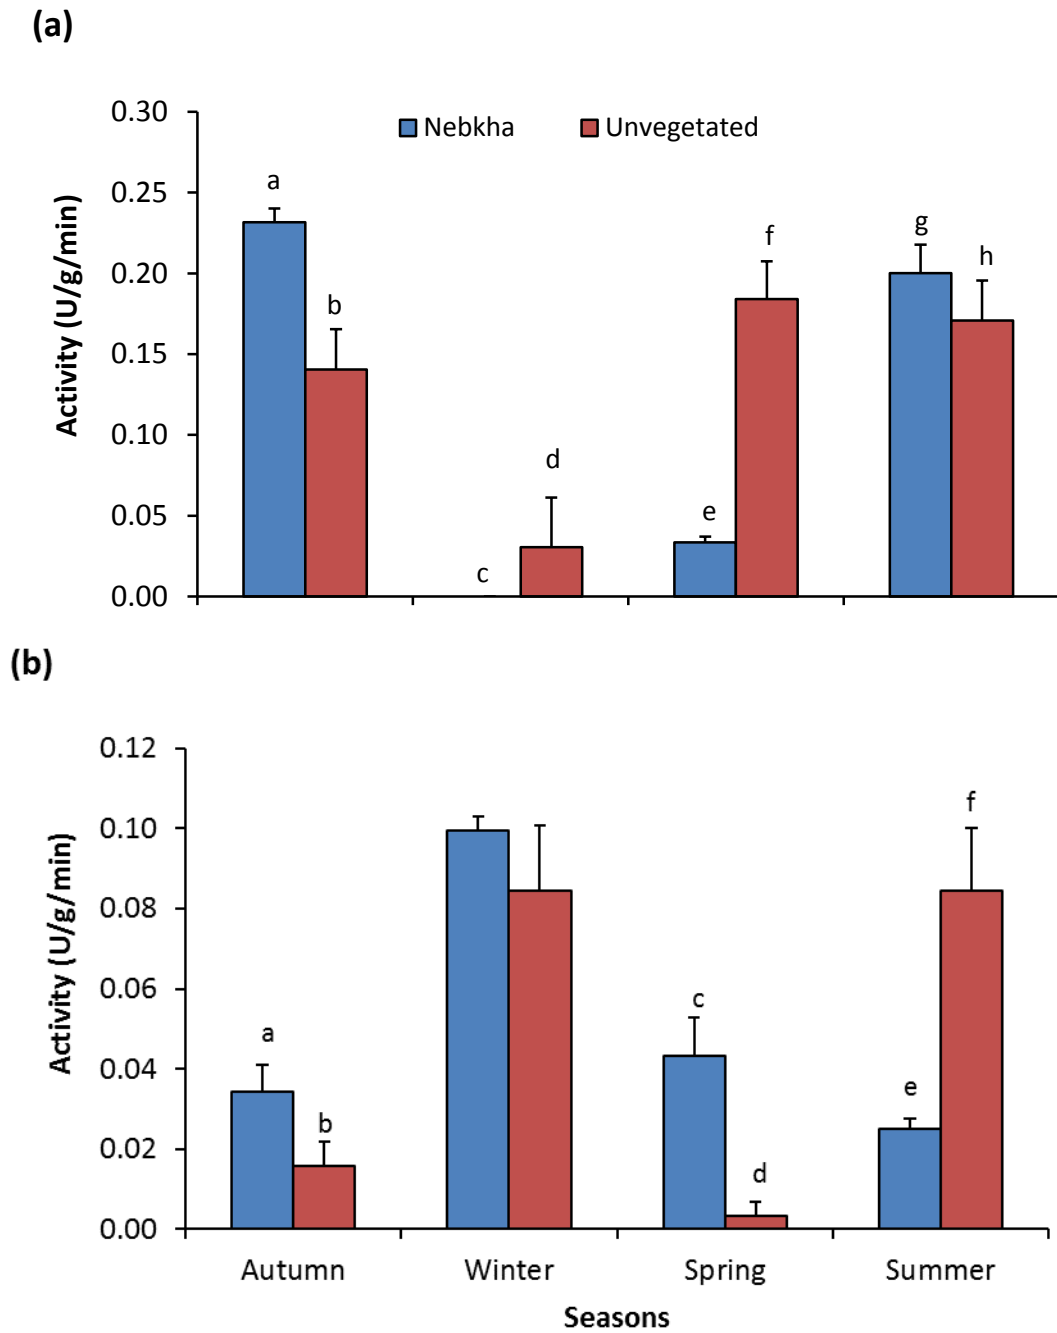

Fig. 3. Seasonal variations in amylase (a) and CMCase (b) enzyme activities of soil collected from nebkhas of *Halocnemum strobilaceum* and unvegetated sites. Bars with lower case letters represent significant difference ($P < 0.05$) between the two sampling locations (nebkha and unvegetated sites).

Generally, soil salinity as indicated by EC- was higher in unvegetated sites compared to nebkhas in all seasons except in autumn. This could be attributed to the high accumulation of salts within the vegetative parts of *H. strobilaceum* (Zahran, 1989 and Zahran & Willis, 2009) that fall on the soil of nebkhas leading salts accumulation under the canopy and increasing soil salinity during autumn (Sarig & Steinberger, 1994). Salinization can be restricted by leaching of salt from root zone so that higher salinities were in unvegetated soil as reported by Shrivastava & Kumar (2014). The lowest salinities were recorded during the growing season in spring. This could be related to the growing season at which *H. strobilaceum* absorb large amounts of salts from the soil, lowering the soil salinity (Zahran & Willis, 2009).

Results reported higher organic matter and total nitrogen contents in the soil of nebkhas of *H. strobilaceum* compared with their unvegetated surrounding soils. Similar findings were also reported by El-Bana et al. (2002a, 2003), Li et al. (2007) and Pool et al. (2013). Such enrichment of these contents in soil of nebkhas could be related to the litter accumulation and decomposition of host plants forming nebkhas and its associated species as well as trapping of materials during wind storms (El-Bana et al., 2003). Li et al. (2007) attributed the differences in total nitrogen and phosphorus due to prolonged microorganism activity that enabled expanded organic matter decomposition.

Soil pH showed differences between nebkha and vegetated sites as well as between different seasons. Such variations could be attributed to nature of organic matter, soil moisture content and decomposition rates of foliage of shrub and annual species in the different locations and seasons (Marcar et al., 1999). For example, the breakdown of accumulated litter and higher microbial activity in the nebkhas under the canopy, may lead to a decrease in soil pH (Ladenburger et al., 2006).

Niemi et al. (2005) suggested that the soil enzyme activities vary seasonally, which depends on the chemical, physical, and biological characteristics of the soil. In the current study, CMCCase enzyme was more active in winter. Previous studies have suggested that the peak of soil enzyme activity does not always appear in the season of higher temperature (Sinsabaugh et al., 1993; Harris & Safford, 1996; Burger & Kelting,

1999 and Criquet et al., 2000). Button (1991) found that bulk (unvegetated) soil is dominated by oligotrophic microorganisms with higher catalytic efficiency as well as rate of dispersion of enzyme-substrate complexes. This finding is supporting higher activities of enzymes noticed in the unvegetated soil.

Amylase enzyme was negatively correlated with moisture as reported by Zaveri et al. (2016). This could be due to the compact of soil by soil moisture. Studies had shown that the compact soil had significantly lower biomass C (38% decrease) and lower enzyme activities (decrease in range from 41-75%) than the uncompacted soil (Orchard & Cook, 1983 and Dick et al., 1988). The organic matter and organic carbon content of soil are accelerated by cellulase, which degrades cellulose in plant debris to glucose, cellobiose and high-molecular-mass oligosaccharides (White, 1982). Thus, CMCCase enzyme activity showed a significant positive correlation with organic matter. It was obvious that total bacterial counts were significantly higher in nebkha than unvegetated sites. This might be due to the nature of root exudates (Zahran, 1997).

Significant negative correlation was found between organic matter and bacterial abundance. Visser et al. (1983) reported that bacteria were enhanced more than fungi and actinomycetes under low nutrient regimes and other environmental stresses in disturbed soils in Alberta, Canada. Yuan et al. (2007) suggested that low soil organic matter and high salinity in soils may produce an unsuitable substrate for the development of fungi and actinomycetes in the microbial biomass. In contrast, high soil organic matter and low salinity in soils may favor fungal dominance in microbial biomass as indicated by high microbial biomass C to biomass N ratio. Bacterial dominance may also inhibit the decomposition of complex organic material in saline soils (Badran, 1994), because fungi are especially important for the breakdown of lignin and cellulose in decaying plant residues (Harper & Lynch, 1985).

Gram-negative bacterial isolates were less than Gram-positive bacteria as the later can better tolerate high matric potential than Gram-negative bacteria because they have stronger cell walls (Martin et al., 1999; Fierer et al., 2003; Schimel et al., 2007 and Vasileiadis et al., 2012). Our results revealed obvious difference

of bacterial composition in different microhabitat of *H. strobilaceum*. Bacterial composition clearly displayed seasonal and spatial variations. More genera were discovered in winter than any other seasons, and some special genera appeared only in specific season. Specific genera were only detected at nebkha and this result is compatible with a study done on rhizosphere of *Salicornia* sp showing that the composition of microbial communities was influenced more by root activity than by soil composition (Mapelli et al., 2013).

It can be concluded that the formation of nebkhas by halophytic vegetation have noticeable effects on accumulation of soil salinity and fertility during different seasons that affect bacterial abundance and activity in coastal environment.

التغيرات الموسمية في خصائص التربة والبكتريا المصاحبة لنباك نبات الحطب الحدادي *Halocnemum strobilaceum* في بحيرة المنزلة، مصر

هبة كمال عيسى¹، مجدى إبراهيم البناء¹، مجدى محسن بهجت²، او محمد إسماعيل أبو ديار³
 اقسام النبات - كلية العلوم - جامعة بورسعيد - بورسعيد - مصر ،²كلية الصيدلة - جامعة جازان - المملكة العربية السعودية و³قسم النبات و الميكروبيولوجى - كلية العلوم - جامعة دمياط - دمياط - مصر.

تتميز النباتات الملحية بقدرتها على تجميع الرواسب المحمولة من قبل الرياح أو الماء في ظلها وتكوين الكتيبات النباتية "النباك" في البيئات الساحلية والصحراوية. ولذلك فمن المهم دراسة الخصائص البيئية والبكتريا المصاحبة لهذه النباتات الملحية. وتعتبر هذه النباك بيئة مناسبة للكثير من العمليات الكيميائية والبيولوجية التي تؤثر على وظائف النظم البيئية. وفي هذا البحث تمت دراسة التغيرات الزمانية في خصائص التربة والتجمعات البكتيرية لمنطقة نباك الحطب الحدادي والمناطق الخالية من الغطاء النباتي في المستنقعات الملحية لبحيرة المنزلة. تم قياس المحتوى الرطوبي ونسبة المادة العضوية والنيتروجين الكلي والفسفور الكلي ودرجة الأس الهيدروجيني ودرجة التوصيل الكهربائي للتربة، وكذلك خصائص المجتمعات البكتيرية وخصائص الإنزيمات المصاحبة. بالإضافة إلى دراسة نسبة إثراء الملوحة والعناصر المغذية في النباك للتعرف على ملوحتها وخصوبتها مقارنة بالبيئات المحيطة. وقد أوضحت نتائج الدراسة أن رطوبة التربة تختلف معنويًا في كل الفصول حيث أن أعلى قيمة لها في فصل الشتاء (16.55%) في المناطق الخالية من الغطاء النباتي. وقد سجلت منطقة النباك أعلى قيم للملوحة ومحتواها من النيتروجين و الفوسفور في فصل الخريف وقد تراوحت نسب الإثراء للنباك في الفصول الأربعة بين 0.31% إلى 4.09% مما يدل على تراكم الأملاح والعناصر المغذية في النباك، ودلت النتائج على التواجد البكتيري دائما أعلى للنباك في كل الفصول. كما تم التعرف على 11 جنسا من البكتريا منتمية إلى Firmicutes، Actinobacteria، Proteobacteria. وأوضحت نتائج الدراسة الاختلاف في ظهور هذه الأجناس في كل من النباك والمناطق الخالية من الغطاء النباتي وكذلك في الفصول الموسمية الأربعة. وبالتالي يمكن الإستنتاج أن النباك التي كونتها النباتات الملحية لها تأثيراً واضحاً على تراكم الأملاح والخصوبة في خلال الفصول الأربعة التي بدورها تؤثر على وفرة وتنوع وأنشطة المجتمعات البكتيرية في البيئات الساحلية.
